Sure, I'd be happy to explain both time complexities in more detail with examples.

1. O(log n):

When we say an algorithm is O(log n), it means that the time complexity grows logarithmically in relation to the input size. As the input size increases, the time it takes to run the algorithm increases at a much slower rate compared to the input size.

Let's take the example of binary search, which is a classic example of an algorithm with O(log n) time complexity.

Binary search works by repeatedly dividing the search space in half. If the search key is less than the item in the middle of the interval, narrow the interval to the lower half. Otherwise, narrow it to the upper half. Repeatedly check until the value is found or the interval is empty.

For example, let's say we have a sorted list of 8 elements and we want to find a certain element:

- Start in the middle: 4 elements on the left, 4 on the right
- If the element is not found, we reduce our search space to half: now we have 4 elements
- Again, start in the middle: 2 elements on the left, 2 on the right
- If the element is not found, we again reduce our search space to half: now we have 2 elements
- One more step might be needed to find the element

So, in this case, we needed log(8) = 3 steps to find the element. That's why we say binary search has a time complexity of O(log n).

2. O(log log n):

O(log log n) is a very efficient time complexity, it grows even slower than O(log n).

This time complexity can be seen in advanced data structures like Van Emde Boas Trees, Fibonacci Heap, etc.

Let's take an example to understand it better. Suppose we have a sorted list of 16 elements and we have a magical algorithm that can reduce the search space to the square root of the current search space in each step.

- Start with 16 elements
- After the first step, we reduce our search space to sqrt(16) = 4 elements
- After the second step, we reduce our search space to sqrt(4) = 2 elements
- One more step might be needed to find the element

So, in this case, we needed log(log(16)) = 2 steps to find the element. That's why we say this magical algorithm has a time complexity of O(log log n).

I hope this helps! Let me know if you have any other questions. 😊
