Copilot

The code you've provided is for generating all possible letter combinations that the number could represent on a telephone keypad. Here's a step-by-step explanation along with a textual tree diagram representation:

1. The `keypad` array represents the letters associated with each number on a phone keypad.
2. The `printCombinations` method is called recursively to generate combinations.
3. It takes three parameters: `number` (the input number as a string), `Index` (the current position in the input number), and `combinations` (the current combination of letters).
4. If `Index` equals the length of `number`, it means we've reached the end, and we print the current combination.
5. Otherwise, we get the current number at `Index`, find the corresponding letters from the `keypad` array, and loop through these letters.
6. For each letter, we call `printCombinations` again with an incremented index and the current letter added to `combinations`.

Here's a simplified tree diagram for input "26":

```
  26
 / | \
a  b  c   <- letters for '2'
|  |  |
m  m  m   <- letters for '6'
```

Each path from root to leaf represents one combination (e.g., "am", "bm", "cm").

The actual tree would have more branches as '6' corresponds to "mno" in the keypad array, but due to screen size limitations, I've shown a simplified version.

When you run this code with "26" as input, it will print:

```
am
an
ao
bm
bn
bo
cm
cn
co
```

These are all possible combinations for "26" based on your keypad mapping.
